On the basis of Quantum Monte Carlo simulations of the two-dimensional Hubbard model which cover the doping range from the under- to the over-doped regime, we find that the single-particle spectral weight $A(\vec{k},\omega)$ qualitatively reproduces both the momentum ($d_{x^2-y^2}$–symmetry) and doping dependence of the pseudogap as found in photoemission experiments. The drastic doping dependence of the spin response $\chi_s(\vec{q},\omega)$ which is sharp in both $\vec{q}\,(\approx(\pi,\pi))$ and ω in the under-doped regime but broad and structureless otherwise, identifies remnants of the antiferromagnetic order as the driving mechanism behind the pseudogap and its evolution with doping.

PACS numbers: 74.20.-z,74.72.-h,75.50.Ee,79.60.Bm

Exciting progress in the microscopic understanding of high-T_C superconductors has recently come from the observation of a normal-state pseudogap of order of the exchange energy J [1] and a lower energy excitation gap of the order of the superconducting gap [1–5]. Angle-resolved photoemission spectroscopy (ARPES) demonstrated that both high- and low-energy gaps are consistent with $d_{x^2-y^2}$–symmetry [1–4]. In addition, both gaps have a more or less identical doping dependence, which may be a key observation to unlocking the mystery of the cuprates: just below optimal hole concentration, the centroids in the spectral weight $A(\vec{k},\omega)$ near $(\pi,0)$ move to higher binding energy, and a portion of the large Fermi surface seems to disappear. These findings have been interpreted as the opening of a pseudogap with maximal energy $J\sim 200meV$ near $(\pi,0)$ [1]. Simultaneously, a normal-state gap with energy $\sim 20meV$, inferred from the leading edge in $A(\vec{k},\omega)$, opens up in this under-doped regime. Both of these gaps vanish in the over-doped regime, and the superconducting gap also rapidly decreases [5]. This empirical correlation between the disappearance of the order J pseudogap and the decrease of superconducting pairing strength suggests that the high-energy features at $(\pi,0)$ are closely related to the pairing interaction [6].

In this letter, we address the microscopic mechanism behind the opening of this pseudogap and its evolution from under-doped to over-doped regimes. We present Quantum Monte Carlo (QMC) simulation results on the two-dimensional Hubbard model with on-site interaction $U=8t$ which demonstrate that the single-particle spectral weight $A(\vec{k},\omega)$ reproduces the most salient ARPES features as function of doping. In particular, the QMC data reproduce the momentum ($d_{x^2-y^2}$–symmetry) and doping dependence of the pseudogap.

Earlier finite-temperature QMC work on the Hubbard model [7,8] has produced results showing a quasi-particle-like band with a dispersion below the Fermi level that is essentially unaffected by doping. On the other hand, groundstate exact diagonalizations [9,10] of the two-dimensional $t-J$ model for small clusters around optimal doping find a signal in the spectral weight corresponding to an insulator-like "shadow" structure; at larger doping this signal vanishes. We present in this work first data of the spectral weight $A(\vec{k},\omega)$ obtained by Maximum-Entropy techniques for previously inaccessible temperatures ($T=0.25t$), showing that if the temperature in the dynamical QMC simulation is lowered below a threshold temperature $T^*\simeq 0.3t$ in the under-doped regime the quasi-particle band is substantially deformed, resulting in the opening of a pseudogap.

Our results provide numerical evidence of earlier theoretical conjectures that the deformation and the pseudogap are intimately related to antiferromagnetic spin fluctuations [11–13]. This is demonstrated by studies of the two-particle excitation spectrum over a wide range of dopings from under-doped to over-doped. They reveal that it is the strongly doping-dependent spin response and not the essentially doping-independent charge response which tracks the doping dependence of the pseudogap. The spin response, $\chi_s(\vec{q},\omega)$, displays a sharp structure in Im χ_s at wave-vector $\vec{q}\cong\vec{Q}\equiv(\pi,\pi)$ and at energy $\omega(\vec{Q})=\omega^*$. Not only near half-filling but also up to optimal doping the spectral weight is distributed around an energy dispersion which still closely follows the spin-wave dispersion $\omega(\vec{q})\sim\omega^{SDW}(\vec{q})$, where ω^{SDW} is calculated within the spin-density-wave approximation. For temperatures $T<T^*$, the antiferromagnetic correlation length $\xi(T)$ becomes larger than the lattice spacing a_0 and, as a consequence, the quasi-particle is strongly dressed by spin fluctuations. As soon as the system enters the over-doped regime, the spin response is no longer sharply peaked near $\vec{Q}=(\pi,\pi)$ and ω^*. It spreads in energy by an order of magnitude (the scale changes from J to $E_{kin}\sim 8t$), and is accompanied by a similar change of the scale of the bandwidth for single-particle excitations. Thus it is this unique doping dependence of the magnetic excitations which establish the pseudogap as being due

to antiferromagnetic spin fluctuations.

The single-band two-dimensional Hubbard model has the standard Hamiltonian

$$H = -t \sum_{\langle ij \rangle, \sigma} \left(c^{\dagger}_{i,\sigma} c_{j,\sigma} + h.c. \right) + U \sum_{i} n_{i\uparrow} n_{i\downarrow} - \mu \sum_{i} (n_{i\uparrow} + n_{i\downarrow}) \qquad (1)$$

on a square lattice, where t is the nearest-neighbor hopping, $c_{i,\sigma}$ destroys a particle of spin σ on site i, and $n_{i\sigma} = c^{\dagger}_{i,\sigma} c_{i,\sigma}$. The chemical potential μ sets the filling $\langle n \rangle = \langle n_{i\uparrow} + n_{i\downarrow} \rangle$. The spectral weight $A(\vec{k}, \omega)$ is inferred from high-quality [14] QMC data by applying state-of-the-art "Maximum-Entropy" techniques [15]. This method has previously been used to resolve a quasi-particle-like dispersive band of width J at half-filling and to follow its evolution from the insulator to the metal [7].

In Fig. 1(a) we compare the QMC results for the single-particle spectral weight $A(\vec{k}, \omega)$ for the under-doped (1% and 5%) and maximally doped (13%) regimes with the ARPES data from Ref. [1] in Fig. 1(b). The theoretical results were obtained for temperatures of $T = 0.33t$ and $T = 0.25t$, on-site Coulomb repulsion $U = 8t$ and 8×8 lattices. To facilitate detailed comparison with Fig. 1(b) of D. S. Marshall, Z.-X. Shen *et al.* [1], we use in Fig. 1(a) the same ω vs $\vec{k}$ "band structure" plot with all spectra referring to the same chemical potential μ ($\omega = 0$).

In accordance with the ARPES data, we find a dramatic change in the electronic structure near $(\pi, 0)$ with doping. In the under-doped (1% and 5%) regime, the features near $(\pi, 0)$ move to lower binding energy as doping is increased. At about 13% doping [8] (full circle in Fig. 1(a)) the pseudogap vanishes.

In addition, a portion of the large Fermi surface, which is closed around (π, π) at $T = 0.33t$ (i.e. has Fermi level crossings between $(\pi, 0)$ and (π, π) as well as between (π, π) and $(0, 0)$), seems to disappear at the lower temperature, $T = 0.25t$. This is indicated in Fig. 1(a) by the downturn of the quasi-particle-like band between $(\pi, 0)$ and (π, π). In the experiment, this behavior in the under-doped regime has been interpreted as the opening of a pseudogap in the underlying Fermi surface near the $(\pi, 0)$ to (π, π) line [1]. The momentum dependence of the pseudogap is also in agreement with experiment in that its largest value, which is of the order of the exchange coupling $J \sim 4t^2/U$, occurs near $(\pi, 0)$ and in that it essentially vanishes along the $(0, 0)$ to (π, π) line. This behavior is consistent with $d_{x^2-y^2}$–symmetry. At 13% doping we obtain a Fermi surface crossing near $(\pi, 0)$ (full circle in Fig. 1(a)) independent of the two chosen temperatures. Thus, at optimal hole doping the Fermi surface is large, consistent with both ARPES [1–4] and earlier QMC calculations [8].

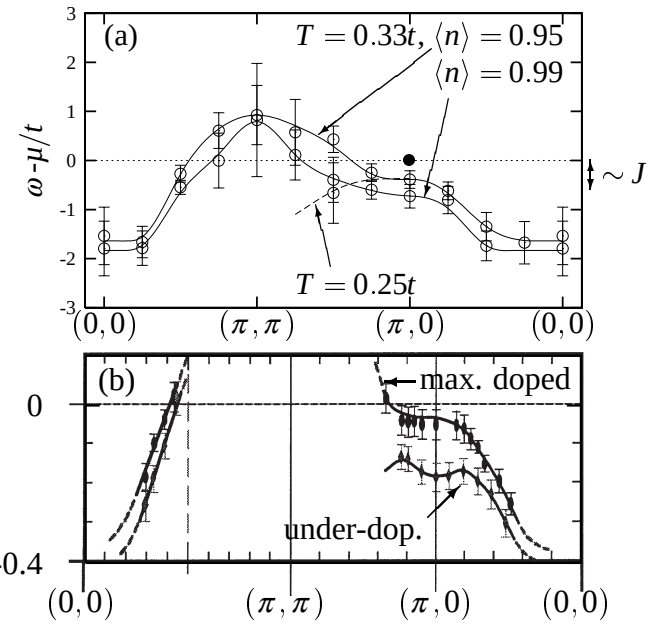

FIG. 1. The dispersion of the peaks in the single-particle spectral weight from (a) QMC simulations of the Hubbard model at densities ranging from the under-doped to the maximally doped regime where peaks in $A(\vec{k}, \omega)$ are represented by error bars and (b) peak centroids in $A(\vec{k}, \omega)$ from under-doped and maximally doped ARPES experiments after Ref. [1].

In the QMC simulation, the opening of a pseudogap in the under-doped regime shows up below a "crossover" temperature $T^* \simeq 0.3t$. To illustrate this crossover, we consider in Fig. 2(a) - 2(b) the role played by temperature and its influence on the spectral weight distribution in more detail. We observe two general features in both spectra: a (several t) broad "incoherent background" both below and above the Fermi surface and a dispersing structure with a smaller width of order of a few J around $\omega = \mu$. In our earlier work [7] in which the lowest temperature accessible was $T = 0.33t$, this dispersing quasi-particle-like band was shown to have its maximum at (π, π). In this case, which is reproduced in Fig. 2(a), there is a "large" Fermi surface centered around (π, π). However, by lowering the temperature to $T = 0.25t$, the structure forming the maximum at (π, π) looses weight and the new valence-band maximum seems to be shifted to $(\pi/2, \pi/2)$ or $(\pi, 0)$ (Fig. 2(b)) [16]. In agreement with the ARPES data in Fig. 1(b), we observe the downturn ("shadow" structure) as well as a drastic (by about a factor of 10) spectral weight loss when following the quasi-particle band from $(\pi, 0)$ to (π, π). It is well known [17] that inclusion of higher-neighbor (t', etc.) interactions lifts the degeneracy of the points $(\pi/2, \pi/2)$ and $(\pi, 0)$ at half-filling and pushes the $(\pi/2, \pi/2)$ point up in energy. This opens up the possibility of a small Fermi surface ("hole pockets") around $(\pi/2, \pi/2)$ [10,18]. The full line in Fig. 2(b), which plots our results for the same temperature for the insulating case, $\langle n \rangle = 1.0$, in-

dicates the similarities between the 7% doped situation and the antiferromagnetic band structure at half-filling.

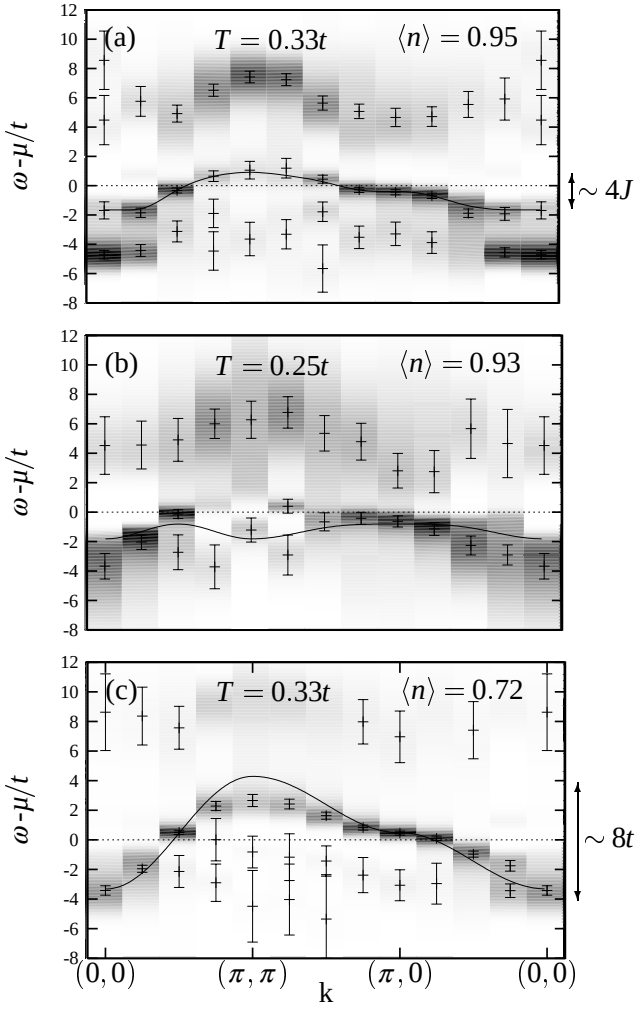

FIG. 2. The QMC spectral weight, $A(\vec{k},\omega)$, of the 8×8 Hubbard model with $U = 8t$ as a function of ω and $\vec{k}$: (a) at temperature $T = 0.33t$ and 5% doping ($\langle n \rangle = 0.95$), (b) at $T = 0.25t$ and 7% doping ($\langle n \rangle = 0.93$) and, (c) at $T = 0.33t$ and 28% doping. Dark (white) areas correspond to large (small) spectral weight. The full lines in (a) and (c) are tight-binding fits to the QMC data, the full line in (b) denotes the $U = 8t$ QMC result for $\langle n \rangle = 1.0$, i.e. the insulating case.

The physical origin of a possible manifestation of insulating band features in the under-doped regime seems to be that around the temperature $T^* \simeq 0.3t$ the antiferromagnetic correlation length ξ becomes larger than the lattice spacing a_0, i.e. for $T = 0.25t$ we find $\xi \simeq 1.2 > 1$, whereas for $T = 0.33t$ we find $\xi \simeq 0.5 < 1$ [19]. The decisive role played by antiferromagnetic spin fluctuations for the pseudogap and the under-doped band structure is substantiated by the behavior of $\chi_{s,c}(\vec{q},\omega)$, shown in Fig. 3.

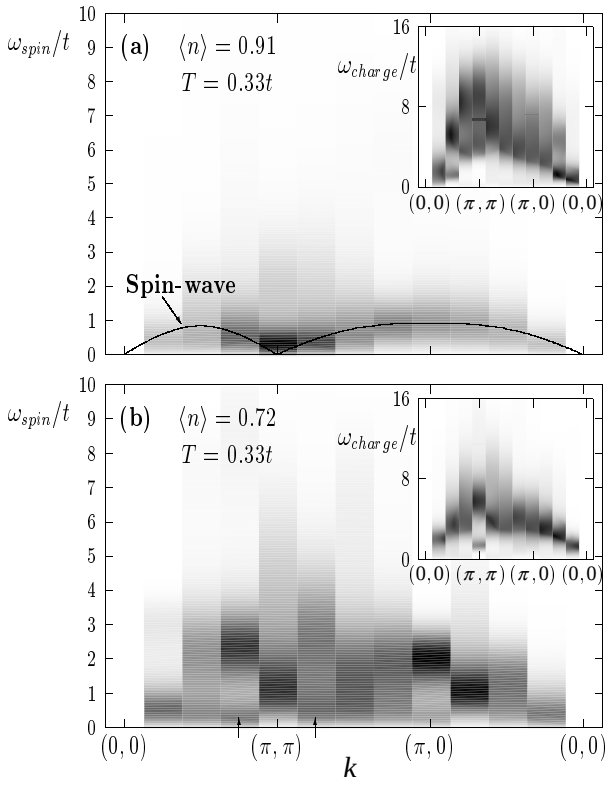

FIG. 3. Two-particle spin (ω_{spin}) and charge (ω_{charge} in the inset) excitations as function of $\vec{k}$, (a) under-doped ($\langle n \rangle = 0.91$), (b) over-doped ($\langle n \rangle = 0.72$). Note the drastic change in the spin response as function of doping.

Consider first Fig. 3(a), which exhibits the spin excitation energy as function of momentum for the 8×8 Hubbard model with $U = 8t$ and $T = 0.33t$ at a doping of 9% away from half-filling. Here, dark (white) areas again correspond to a large (small) spectral weight for spin excitations and the full line gives the spin-wave dispersion, i.e. $\omega^{SDW}(\vec{q}) = 2J(1 - (\varepsilon_{\vec{q}}/4t)^2)^{1/2}$, where $\varepsilon_{\vec{q}}$ denotes the tight-binding energy $\varepsilon_{\vec{q}} = -2t(\cos(q_x) + \cos(q_y))$. This figure reveals that in the under-doped regime up to maximal doping (13%) the spin excitations have an energy dispersion that still closely follows the antiferromagnetic spin-wave dispersion. The main weight is confined to $\vec{Q} = (\pi,\pi)$ with a small spread $\Delta\vec{Q}$ and to a small but finite energy $\omega(\vec{Q}) = \omega^*$. This sets an energy scale J for spin excitations. This result is in accordance with recent neutron-scattering data [20] and also with other experiments that have directly shown that propagating spin-waves with energies of order J still exist even at optimal doping [21]. When the temperature is lowered below $T^* \simeq 0.3t$, $\Delta\vec{Q}$ slightly decreases and the antiferromagnetic correlation length $\xi(T)$ ($\sim 1/\Delta Q$) becomes larger than the lattice spacing. As a consequence, the single-particle hopping is now strongly renormalized by the short-range antiferromagnetic order resulting in a bandwidth (Fig. 2(b)) also of order of (a few) J. This renormalization is strongest at $(\pi,0)$ and, thus, directly

responsible for the pseudogap: because of the "matching"condition, $(\pi,0) \pm \vec{Q} = (0,\pi)$, the bare photohole created by ARPES for $\vec{k} = (\pi,0)$ couples strongly to two-particle excitations whose spectral function peaks near momentum $\vec{Q} = (\pi,\pi)$ [6]. Using a standard diagrammatic evaluation of the self-energy like the FLEX summation [22], and approximating the peak in Im $\chi_s(\vec{q},\omega)$ by Im $\chi_s \sim \delta(\vec{q}-\vec{Q})[-\delta(\omega-\omega^*)+\delta(\omega+\omega^*)]$, one obtains for $\omega < -\omega^* < 0$ the self-consistency equation

$$A(\vec{k},\omega) \simeq \frac{U^2 A(\vec{k}-\vec{Q},\omega+\omega^*)}{\left[\left(\omega - \varepsilon_{\vec{k}} - \text{Re }\Sigma(\vec{k},\omega)\right)^2 + \text{Im }\Sigma(\vec{k},\omega)^2\right]}, \quad (2)$$

since $\text{Im}\Sigma(\vec{k},\omega) \sim -U^2 A(\vec{k}-\vec{Q},\omega+\omega^*)$. As a consequence of this self-consistency requirement, multiple, repeated spin-wave excitations ("shake ups") accompany the bare carrier motion, lead to incoherent contributions to the electronic spectrum at $(\pi,0)$ and spread spectral weight to lower energies. In the over-doped regime, shown in Fig. 3(b), the sharpness both in $\vec{q}$ and ω in Im $\chi_s(\vec{q},\omega)$, and thus the "matching"condition is lost completely and the coupling to the bare photohole is weak and broad in energy. The crossover to a new energy scale (t rather than J) is also reflected in a corresponding crossover in the single-particle bandwidth ($\sim 8t$) in Fig. 2(c). In contrast to the spin excitations, the charge excitations are already broad and structureless in the underdoped regime, with the energy spreading essentially over the non-interacting bandwidth $\sim 8t$ (inset in Fig. 3(a)) [23].

In this letter, we have addressed the microscopic mechanism behind the opening of a pseudogap and its evolution from under-doped to over-doped regimes. Our key results are (i) that the dynamical QMC results for the two-dimensional Hubbard model reproduce both the momentum (i.e. the $d_{x^2-y^2}$–symmetry) and doping dependence of the pseudogap and (ii) that it is the unique doping dependence of the magnetic response which establishes the first numerical proof that the pseudogap is due to antiferromagnetic spin correlations in the underdoped regime.

[16] Because the integrated spectral weight suffers less from resolution problems of the Maximum-Entropy technique, we examined in detail the temperature dependence of the total spectral weight in the quasi-particle band at (π,π). This signal is calculated from the percentage of weight in this band (which is above the chemical potential μ and well separated from the incoherent background, see Fig. 2(a)) with respect to the total intensity, $\int_{-\infty}^{+\infty} d\omega A(\vec{k},\omega) = 1$. At $T = 0.5t$ and $\langle n \rangle = 0.93$ we have $\approx 14\%$ intensity, at $T = 0.33t$ we get $\approx 9\%$ and, finally, less than 5% at $T = 0.25t$. In ARPES a weak signal with less than roughly 10% intensity of the largest signal (located both in theory and experiment at $(\pi/2,\pi/2)$) is not observable [9]. In a similiar way our QMC results in Fig. 2(b) at $T = 0.25t$ can be interpreted: the resolution of the Maximum-Entropy technique for the QMC error level at this temperature is such that peaks with relative intensities less than about 10% will not be resolved. This is the criterion followed in this work to classify a result as observable in the dynamical QMC method.
